Slide 2

Slide 3

Tonight I am going to speak about a unique unique telescope - the only telescope in the southern hemisphere designed to look at the Northern Sky !

Slide 4

### Neutrinos & Muons

- ✦ The Neutrino is an atomic particle that has no charge, almost no mass and travels at almost the speed of light. It is created in nuclear reactions. It has a very long life but appears to oscillate between flavours.
- ✦ The Muon is a charged particle that is very similar to the electron but has 270 times the mass. It is very short lived. As a result they do not exist naturally on (or in) the Earth.

Explain that the Neutrino is very unlikely to react with any matter

Slide 5

### Detecting Neutrinos

- ✦ The problem with detecting Neutrinos is that they very rarely interact with anything - you need around 5 light years of lead to stop half of them ! The fraction of a light second of rock that is the Earth is insignificant against this amount of material.
- ✦ However there are 65 Billion going through each square inch of the Earth per Second ( Including you)
- ✦ Very rarely the Neutrino bumps into an atom and destroys it creating a Muon travelling very close to the speed of light as part of the debris.

The 65 Billion are from the Sun - it does not matter if it is nighttime they just go through the Earth without noticing !

There are other sources as well including Nuclear Reactors & Natural Radioactivity.

As a trillion or so are passing through you a second it is a good thing they do not interact !

Slide 6

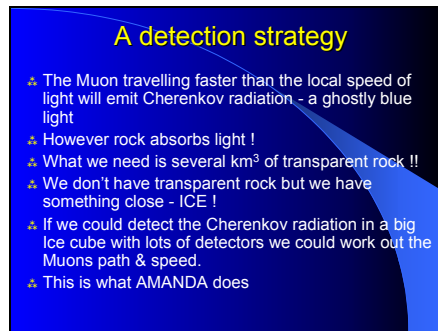

### Detection of Muons

- ✦ Muon is charged so one should be able to detect it
- ✦ Calculations of the Number of Muons from Astronomical Events shows you need a detector of several km<sup>3</sup>
- ✦ Not possible to build an electrical detector this big to look for a single moving particle that looks like an electron !
- ✦ Muon travelling faster than speed of light in a solid

While the Muon is charged it has a short life so detecting it by it's electrical field in rock is impossible at present.

Rock is also not a very good detector as it is radioactive and thus produces 'natural' muons.

Slide 7

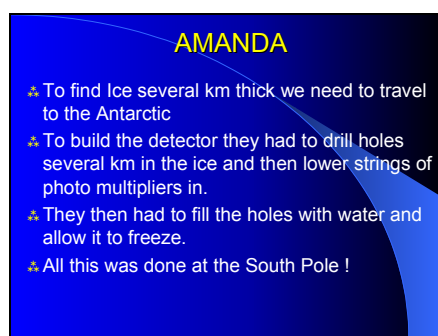

### A detection strategy

- ✦ The Muon travelling faster than the local speed of light will emit Cherenkov radiation - a ghostly blue light
- ✦ However rock absorbs light !
- ✦ What we need is several km<sup>3</sup> of transparent rock !!
- ✦ We don't have transparent rock but we have something close - ICE !
- ✦ If we could detect the Cherenkov radiation in a big ice cube with lots of detectors we could work out the Muons path & speed.
- ✦ This is what AMANDA does

We need detectors all round the block of ice to allow us to triangulate the path

Ice in the Antarctic also has a low level of natural radioactivity.

Slide 8

### AMANDA

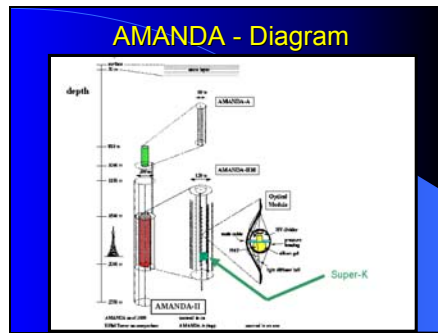

- ✦ To find Ice several km thick we need to travel to the Antarctic
- ✦ To build the detector they had to drill holes several km in the ice and then lower strings of photo multipliers in.
- ✦ They then had to fill the holes with water and allow it to freeze.
- ✦ All this was done at the South Pole !

Freezing of course applies great pressure to the detectors, just like your pipes bursting in the cold at home - so they and the cable connections had to be engineered to withstand this.

The ice is only transparent to the Blue Light at depths > 1,400m this defines the height of the top of the string together with -It also has to be deep to stop the Muons generated in the Atmosphere by cosmic rays interfering.

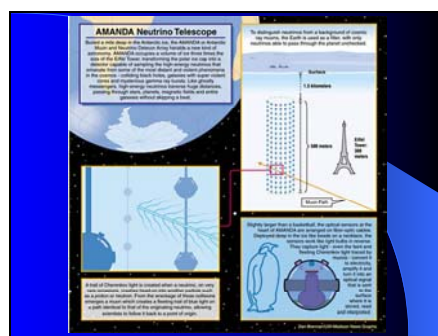

The detector arrays extend from 1,300m to 2350m currently 19 strings with 680 detectors in total

Slide 9

Note the size of the detector relative to The Eiffel Tower as well as Super-Kamiokande the Japanese Neutrino detector (the green cube).

Slide 10

Another diagram,

Beware top right is not to scale

Slide 11

The detectors are photo multipliers in a pressure proof transparent sphere

THE PMT multiplies the light by at least 100 million times and can detect single photons.

Slide 12

Hole drilled with hot water  
Hole is about 0.5 m diameter  
and 2350 m deep !

When the string of detectors is lowered into position the hole is back filled with water that then freezes.

Slide 13

You may think building a detector in Antarctica is very expensive but building a conventional neutrino detector with of piles of ultra pure lead to shield an above ground detector has been estimated to cost 10 k dollars / sq m. So a km sq array is  $10E6 \times 10E4 = 10E10 = 10 \text{ Billion Dollars !}$

In fact the US has got quite a good science infrastructure at the South Pole and it is not too difficult to work there in the Antarctic Summer.

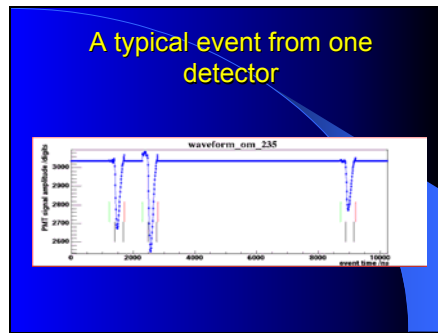

Slide 14

The electronics looks for the light pulses and times them very accurately. By timing when the light arrives at each detector it is possible to plot the path of the Muon through the detector. This then gives you the path of the original Neutrino (within 0.6 degrees).

Time resolution is 3ns ( light travels 3 feet in this time)

Slide 15

The flat parts of the trace are where the uninteresting bits have been cut out.

Slide 16

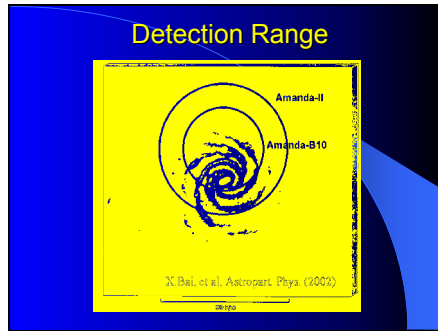

Explain !

Slide 17

- What do we expect to see ?
- ✦ The high energy neutrinos the telescope can see are generated in highly energetic astrophysical events such as:
  - ✦ Formation of Black Holes
  - ✦ Collision of White Dwarfs or Neutron Stars
  - ✦ The sources of Gamma Ray Bursts
  - ✦ Quasars
  - ✦ (Supernova)

Explain the phenomena  
The first ones generate very high energy neutrinos which will directly create Muons that can be detected.  
Galactic Supernova are too low an energy to be detected

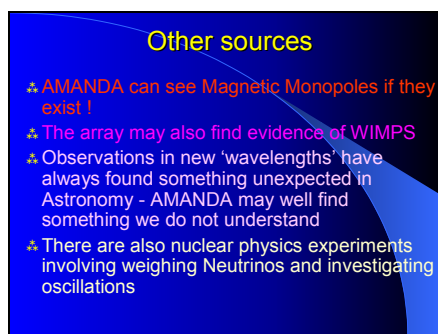

Slide 18

Detection range for supernova.

This is a lot lower than for other (higher energy !) events as the Neutrinos only have a low energy of around 20eV, detection is via a secondary phenomena.

Slide 19

Magnetic Monopoles MAY be part of dark matter

WIMPS - some may collide with atoms in the earth and get slowed down and captured - they may then annihilate a bit of matter producing Neutrinos

Neutrinos are now believed to have mass and oscillate between the three 'flavours' - Electron Neutrino, Muon Neutrino or Tau Neutrinos. (Tau is like a much heavier electron or Muon )

Slide 20

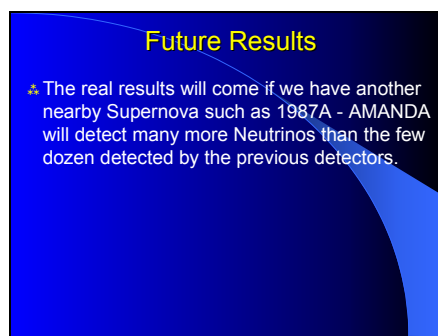

1555 events

The horizontal band is due to Muons from Atmospheric Cosmic Rays entering the ice from the edge and is to be expected.

There is no statistical evidence from the initial data for any point sources of Neutrinos in the Northern Sky. Though there is a hint that Markarian 501 ( a BL Lac object - elliptical galaxy with a compact highly variable nucleus) may have been detected but it was not very active during the observation period.

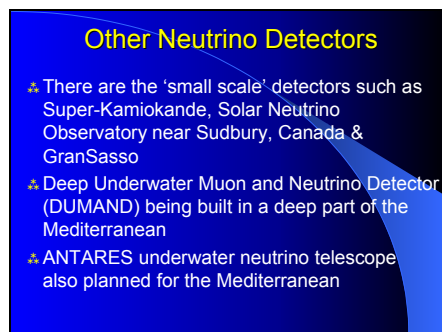

Slide 21

**Future Results**

- ✧ The real results will come if we have another nearby Supernova such as 1987A - AMANDA will detect many more Neutrinos than the few dozen detected by the previous detectors.

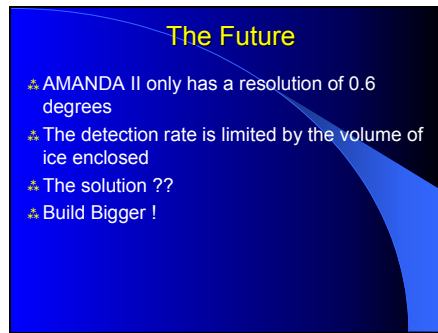

Slide 22

**Other Neutrino Detectors**

- ✧ There are the 'small scale' detectors such as Super-Kamiokande, Solar Neutrino Observatory near Sudbury, Canada & GranSasso
- ✧ Deep Underwater Muon and Neutrino Detector (DUMAND) being built in a deep part of the Mediterranean
- ✧ ANTARES underwater neutrino telescope also planned for the Mediterranean

Slide 23

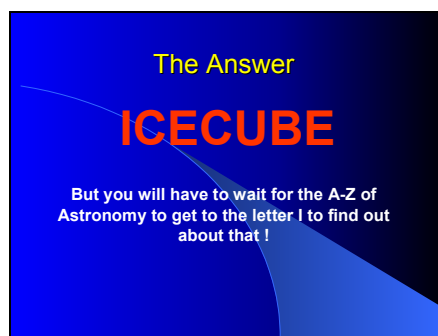

The Future

- ✦ AMANDA II only has a resolution of 0.6 degrees
- ✦ The detection rate is limited by the volume of ice enclosed
- ✦ The solution ??
- ✦ Build Bigger !

This slide features a dark blue background with a lighter blue curved shape on the right side. The title 'The Future' is in yellow. The list items are in white with a small yellow star icon.

Slide 24

The Answer

# ICECUBE

But you will have to wait for the A-Z of Astronomy to get to the letter I to find out about that !

This slide features a dark blue background with a lighter blue curved shape on the right side. The title 'The Answer' is in yellow. The word 'ICECUBE' is in large, bold, orange letters. The text below is in white.
